ABSTRACT

Aquatic macrophytes provide structures to be colonized and used as refuge, shelter and feeding sites by many organisms. As ecosystem engineers, they also have major effects on the physical and chemical features of water and sediment. Low oxygen concentrations are one of the recurrent impacts of dense beds of aquatic macrophytes, so the macroinvertebrates that inhabit macrophyte beds may have to cope with hypoxia. This study tested the survival of six groups of macroinvertebrates associated with different species of macrophytes (Trapa natans or submerged species) under hypoxia. The hypothesis tested was that the organisms that inhabit stands of the invasive T. natans are more resistant to low oxygen concentrations than those that inhabit submerged aquatic vegetation (SAV). Chironomids and amphipods associated with T. natans were more resistant than those associated with submerged species. Gastropods, ostracods and planarians from the two habitats were equally resistant to hypoxia, with high survival in both cases. Zygopterans were the most impaired group, with no survival at all. The results indicate the responses to hypoxia vary among groups, and so do the mechanisms through which they occur.

INTRODUCTION

Biological invasions have become one of the greatest threats to the integrity of Earth’s ecosystems (Strayer 2010). Invasive species are usually exotic (but not always) to the habitat they colonize and very successful in them, often to the detriment of the former inhabitants. They bring in new traits that represent new pressures to the system, frequently culminating in undesirable impacts to native communities and the environment. In freshwater habitats, which are especially sensitive to anthropogenic impacts (Dudgeon et al. 2006), invasions are recurrent and their effects have become obvious and a cause of concern (Strayer 2010).

Aquatic macrophytes create distinctive habitats within aquatic ecosystems. They provide structures to be colonized by an array of organisms, and are used as refuge, shelter and feeding sites (Agostinho et al. 2007; Mormul et al. 2010). They also have major effects on the physical and chemical features of water and sediment (Urban et al. 2009; Bini et al. 2010; Kleeberg et al. 2010; Tall et al. 2011; Rodriguez et al. 2012), and, because of that, are considered ecosystem engineers (Bouma et al. 2005; Caraco et al. 2006). When macrophytes are invasive, their “engineering” can become a problem if it causes changes that the original inhabitants of the invaded area cannot cope with. Macrophytes have a great potential of becoming invasive because they adapt easily to a large range of habitats, have high rates of vegetative reproduction and fast growth (Santamaria 2002).

A few macrophyte traits are often related to impacts in their environment and to other organisms when they become invasive. Biomass production, photosynthesis and decomposition, for example, are three functions through which macrophytes can alter...
habitat complexity, light penetration, pH and dissolved oxygen concentration (Schultz and Dibble 2012). Low oxygen concentrations have been identified as one of the recurrent impacts of dense growth of aquatic macrophytes (Caraco et al. 2006; Bunch et al. 2010; Turner et al. 2010; Desmet et al. 2011). Overnight respiration in large macrophyte beds usually creates a daily variation pattern in dissolved oxygen (DO) levels, with lower values at sunrise and higher values when light is most available for photosynthesis (Jones et al. 1996; Miranda et al. 2000; Thomaz et al. 2001; Colon-Gaud et al. 2004). Besides plants’ metabolic activities, oxygen dynamics also depend on the physical structure of the stands, as they regulate light incidence and water circulation (Jones et al. 1996; Miranda and Hodges 2000; Bunch et al. 2010). In floating-leaved and emergent species, for example, the diel pattern can be overcome by the constant shading and reduced exchange at the water-air interface caused by the biomass that lies above the surface. Furthermore, the oxygen produced during photosynthesis by the aerial biomass is liberated to the atmosphere while the oxygen dissolved in the water is still consumed by respiration and decomposition. This unbalanced uptake can lead to more prolonged hypoxia or anoxia in dense beds of floating-leaved or emergent plants, which has been shown to occur in many macrophyte beds (Bunch et al. 2010; Turner et al. 2010; Desmet et al. 2011), among them water-chestnut beds in the Hudson River (Caraco and Cole 2002).

The water-chestnut *Trapa natans* L. is native to temperate and tropical Eurasia and Africa (Crow and Hellquist 2000), and was introduced in the United States in 1874 (Hummel and Kiviat 2004). In 1930, it reached the Hudson River (Hummel and Kiviat 2004), where it is now widespread, forming stands of hundreds of hectares (Nieder et al.
This macrophyte is rooted in the sediment, with a submerged stem and feather leaves, and a dense canopy of floating leaves (Hummel and Kiviat 2004). *T. natans* has already replaced part of the native aquatic vegetation, dominated by the submerged species *Vallisneria americana* Michx. (water-celery), in many parts of the Hudson River (Strayer et al. 2003). The native *V. americana* is also rooted in the sediment, but its leaves are long and flat, grow from rhizomes, and the whole plant is submersed. Such different growth forms, shown in Figure 1, create distinct habitats for all macrophyte-associated organisms, as much in their physical structuring as in their influence on physical and chemical parameters of water and sediments.

![Figure 1. Comparison between the submerged growth form of *Vallisneria americana* (water-celery) and the floating-leaved form of *Trapa natans* (water-chestnut).](image)

The case of *T. natans* in the Hudson River has been thoroughly investigated (Caraco and Cole 2002; Hummel and Findlay 2006; Goodwin et al. 2008). Tidal
influence has been shown to add to its engineering on DO dynamics. Caraco and Cole (2002) showed that the DO levels in *T. natans* beds varied in a 12.5 h tidal cycle, with high peaks (ca. 7.5 mg.L\(^{-1}\)) during high tides as fresh, well-oxygenated water flows in from the open water of the river, and lows of 0 to 2.5 mg.L\(^{-1}\) during low tides. In *V. americana* stands however, DO never dropped below 5 mg.L\(^{-1}\) and was always higher than in the open water surrounding the bed (Caraco and Cole 2002). Therefore, the hypoxic to anoxic events that take place in *T. natans* beds are temporally limited by the tides, lasting approximately six hours with DO values from 0 to 2.0 mg.L\(^{-1}\) (Caraco and Cole 2002). These low DO values could be maintained for much longer periods in large beds that are not subjected to periodic flushes of oxygen-rich water.

Such different habitats created by *T. natans* in relation to the former dominant species *V. americana* could have led to changes in the macrophyte-dwelling communities. Strayer et al. (2003) compared the communities of aquatic macroinvertebrates in stands of *T. natans* and *V. americana* in the Hudson River. They found that although some community attributes, such as species richness and diversity, did not differ between the native and invasive stands, taxonomic composition differed greatly. The ability of species to deal with the distinctive dissolved oxygen dynamics with its periodic hypoxic events was thought to explain part of the differences between *T. natans*- and *V. americana*-associated macroinvertebrate communities, along with predator pressure and food availability, both which would also be influenced by *T. natans* engineering (Strayer et al. 2003). Kornijów et al. (2010) attempted to unveil the role of dissolved oxygen dynamics in determining the macroinvertebrate community in *T. natans* beds. They found that species richness, diversity and density did not differ among
microhabitats (beds’ edges versus center; leaves versus sediments) with different degrees of oxygen depletion in *T. natans* beds, meaning that the macroinvertebrates inhabiting these beds can and do cope with periodic short-term hypoxia.

Dissolved oxygen concentration in aquatic habitats has diverse effects on the physiology, behavior, life cycle, growth capacity, distribution, reproductive success and immunological system of animals (Ekau et al. 2010). Morphological, physiological and behavioral adaptations to low levels of dissolved oxygen have been reported for many aquatic organisms, including auxiliary respiratory appendages (Robinson et al. 1991; Marziali et al. 2006), migration to oxic microhabitats (Apodaca and Chapman 2004; Sesterhenn et al. 2013), use of atmospheric air (Hanley and Ultsch 1999; Seuffert and Martin 2010; Penha-Lopes et al. 2010), induction of respiratory pigments (Spicer 1993; Panis et al. 1996) and anaerobic metabolism (Frank 1983; Hamburger et al. 1995; Hamburger et al. 2000).

The aim of this study was to investigate whether the organisms that inhabit stands of the invasive *T. natans* are more resistant to low oxygen concentrations than those that inhabit submerged aquatic vegetation (*V. americana* and *Myriophyllum spicatum* L. (European milfoil)) stands. This study also aims to discuss which adaptations could provide *T. natans*-dwelling macroinvertebrates with a better capacity to cope with hypoxia.
METHODS

Study area

The North and South Tivoli Bays, shown in Figure 2, encompass ca. 290 ha of freshwater tidal marshes, subtidal shallows and intertidal mudflats, along 3 km of the eastern shore of the Hudson River. The marshes are dominated by narrow-leaved cattail (*Typha angustifolia* L.), the subtidal shallows are dominated by the submerged species *V. americana* and *M. spicatum*, and the South Bay mudflats are dominated by the invasive *T. natans* (Yozzo et al. 2005). All these macrophytes have been shown to support dense and diverse macroinvertebrate communities (Strayer et al. 2003; Kornijów et al. 2010; Yozzo and Osgood 2013). These areas are also used by many fishes, such as black bass (*Micropterus sp.*), white perch (*Morone americana*) and common carp (*Cyprinus carpio*), waterfowl, many birds, and snapping turtles (Yozzo et al. 2005).
Figure 2. Sampling sites in the Tivoli North and South Bays.

Experiments

Sampling occurred from mid August until late September 2013, a period that encompassed peak biomass for invasive *T. natans* (coded “TNA” throughout), and for
submerged *V. americana* and *M. spicatum* (coded “SAV” throughout) (Caraco and Cole 2002). Animals were collected from a large TNA bed in Tivoli South Bay and from an SAV bed in Tivoli North Bay by putting whole plants into a submerged bucket, gently shaking them, pouring the water into a plankton net (118 µm mesh size) and collecting the retained material, which often included mud and debris, in jars. In SAV beds, some samples were collected by sweeping the net in the beds to avoid destroying the plants. All collected material was kept on ice and immediately taken to the lab for sorting.

Organisms were sorted under a stereomicroscope, separated by groups and kept in jars with river water. The most abundant groups in the samples were Chironomidae, Gastropoda, Amphipoda, Ostracoda, Zygoptera and Planariidae. All jars were kept in a large tray containing water and ice packs to keep temperature low. With the exception of Amphipoda, no organisms were kept longer than 24 hours before the trials, and the Amphipoda that were kept longer (up to five days) were in a large plastic tray (ca. 10 L) with an air pump providing high oxygen levels, and live chironomids were added as food.

To determine the resistance of organisms to hypoxia, a series of laboratory assays were run by manipulating dissolved oxygen levels and measuring the survival of different invertebrates. River water was sparged with N₂ gas until low concentrations of DO (0.5 to 1.0 mgO₂.L⁻¹) were achieved for the hypoxic treatment and aerated (when necessary) until saturation for the normoxic treatment (8 - 9 mgO₂.L⁻¹). These concentrations are within the range of variation found by Caraco and Cole (2002) in TNA (low DO) and SAV (high DO) beds. The assays were run in 300 ml biological oxygen demand bottles. Water temperature was not controlled and averaged 22.2±0.7°C (mean±SD). After all bottles were filled with water, and oxygen and temperature were measured with a
handheld YSI ProODO meter, the organisms were added and bottles sealed. Each trial consisted of one group being tested in a set of five replicates for each treatment, run according with organism’s availability. In a few cases, only three replicates were run, or the five replicates were run in blocks of two and three replicates. Five individuals were used in each bottle with the exception of ostracods, for which ten individuals were used per bottle.

Two different exposure times were tested: six hours, which was based on the length of hypoxic events observed in the Hudson River (Caraco and Cole 2002), and eighteen hours, which meant to represent an environment without tidal influence and consequently longer hypoxic periods. At the end of each trial, DO and temperature were measured in each bottle and the organism’s survival was verified. Animals were checked, under magnification when necessary, and considered alive when moving spontaneously or in response to touching. The total number of organisms recovered, which differed for some groups from the initial number probably due to predation and/or difficulties in handling, was used to calculate the survival percentage. All organisms were kept in 70% alcohol for later taxonomic identification.

**Statistical analysis**

Welch t-tests (Welch 1947) were used to test for differences between the survival of organisms from different origins (TNA vs. SAV) within each taxonomic group (Amphipoda, Odonata, Gastropoda, Chironomidae, Ostracoda and Planariidae) and exposure time (six and eighteen hours). A paired Welch t-test was also run including data from all taxonomic groups to test for differences in survival between origins within
each exposure time. In all analyses, the response variable was the percentage of survival in the hypoxic treatment divided by the percentage of survival in the normoxic treatment. Tests were performed with R (R Core Team 2013).

RESULTS

DO initial and final concentrations in hypoxic treatments averaged 0.69±0.2 mgO₂.L⁻¹ and 0.25±0.3 mgO₂.L⁻¹, while normoxic concentrations averaged 8.65±0.3 mgO₂.L⁻¹ at the beginning of experiments and 7.29±1.5 mgO₂.L⁻¹ at the end. The normoxic controls of all trials (SAV and TNA, 6 and 18 hours, n=117) averaged 97±9% of survival, which indicates that handling and experimental conditions did not by themselves kill many animals; however, the survival values used in the analyses did take into account the survival in normoxic treatments, as mentioned in methods.

The results of t-tests can be seen in Table 1 and in Figure 3. When all taxa were considered, there were no significant differences in survival between organisms associated with TNA or SAV beds for either exposure time. When each taxonomic group was tested separately, significant differences were only found for Amphipoda in the six hour trial and for Chironomidae in the eighteen hour trial. Both groups showed higher survival of organisms associated with TNA rather than SAV, as predicted in the hypothesis. Nevertheless, none of the remaining groups (Zygoptera, Ostracoda, Gastropoda, Planariidae) differed in their survival according to organisms’ origin.

Zygoptera had no survival at all in low DO at either exposure time and regardless of the origin of the organisms. On the other hand, Ostracoda had high survival in all hypoxic treatments, independent of originating from TNA or SAV.

When considering all groups, Amphipoda, Gastropoda and Chironomidae, survival was higher in the six hour trials than in the eighteen hour ones. Moreover, when survival between origins in different exposure times was compared, there seemed to be an interaction between these factors, with a smaller difference between origins in the six hour treatment than in the eighteen hour one.
Figure 3. Survival under hypoxia (mean ± standard error) of organisms associated with *T. natans* (TNA) and submerged aquatic vegetation (SAV) in six (■) and eighteen (●) hours exposure. The * indicates significant difference between TNA and SAV (*p* < 0.05).
DISCUSSION

Mixed support was found for the hypothesis that macroinvertebrates associated with TNA beds are more resistant to hypoxia than those inhabiting SAV. Data for Amphipoda and Chironomidae supported this hypothesis, while data for the other tested groups did not. Thus, the results indicate that the differences in community composition found by Strayer et al. (2003) between TNA and *Vallisneria americana* (which is one of the two species in SAV) stands can be attributed only in part to differential resistance to hypoxia.

The mechanisms involved in some groups’ resistance to hypoxia can only be inferred to a certain extent. Higher survival of Chironomidae associated with TNA could be related to the presence of hemoglobin in animals living in TNA beds and its absence or lower quantity in SAV organisms, since there is great inter-specific variation in hemoglobin content among chironomids (Panis et al. 1996). However, Strayer et al. (2003) found more hemoglobin-bearing chironomid species in *V. americana* than in TNA beds, so this might not be the main mechanism here. Chironomids also possess morphological adaptations, such as thoracic horns and fringed anal lobes that tend to be more developed in species coping with low DO (Marziali et al. 2006). These structures, together with undulatory movements of the abdomen (Panis et al. 1996), can increase ventilation, but the animals would still rely on DO. It has been shown though that some chironomids can turn to an anaerobic metabolism that could give them resistance to short (a few days) and even long-term (a few months) hypoxia (Frank 1983; Hamburger et al. 1995; Hamburger et al. 2000). Species differ in their ability to perform anaerobic
metabolism (Frank 1983), and this could account for the higher survival of TNA-dwelling chironomids in relation to the SAV ones.

The other group that showed higher survival to hypoxia when collected from TNA beds was Amphipoda, in the six hour trials. In the eighteen hour trials, however, all animals died, revealing that their resistance is limited to short-term exposure to hypoxia. Previous studies (Hoback and Barnhart 1996; Spicer et al. 2002) showed that the species *Gammarus pseudolimnaeus* and *Gammarus pulex* were highly sensitive to low DO, with up to 100% mortality in 90 minutes of anoxic conditions for *G. pulex*. An attribute that could enhance survival of amphipods in low DO environments would be their ability to escape to more oxygenated areas due to their good swimming skills; however, in this experiment, this mechanism was impaired because the animals were enclosed in an arena with uniformly low DO. Moreover, in the field, this behavior might increase predation risk and thus mortality (Kolar and Rahel 1993). The presence of the respiratory pigment hemocyanin was demonstrated in many amphipods (Stucliffe 1984; Spicer 1993) and it might be an important physiological adaptation to hypoxia. On the other hand, a low DO-induced anaerobic metabolism was shown to be poor and of little importance for *G. pulex* (Spicer et al. 2002), so the survival during short-term hypoxia of Amphipoda species in this experiment is more likely to be related to the presence of respiratory pigments.

Out of the groups tested, Zygoptera was the most strongly impaired by hypoxia, with no survival at all in low DO at either exposure time and regardless of the origin of the organisms. As tracheal gill breathers, they do tend to be more sensitive to hypoxia than other groups (Chapman et al. 2004). It was also observed that these animals were much more abundant in SAV (data not shown), meaning that DO might play a part in
their distribution. They possess a morphological accessory, their caudal lamellae, that can assist oxygen uptake among other functions (Apodaca and Chapman 2004; Sesterhenn et al. 2013); however, even though most of the animals used had their lamellae intact, they did not survive even the short-term hypoxia. This suggests they must possess some kind of behavioral adaptation to escape it, since they were found in TNA beds. In fact, this group is known to migrate towards the water’s surface to find higher DO concentrations (Robinson et al. 1991; Apodaca and Chapman 2004; Sesterhenn et al. 2013). This might be an important mechanism for the Zygoptera in Hudson River habitats, since Strayer et al. (2003) found them to occur on plants but not sediments, and Kornijów et al. (2010) collected them from TNA leaves but not from other parts of the plants, suggesting a dependence on more oxygenated areas of TNA beds.

At the other extreme, Ostracoda were highly resistant to hypoxia, even in the eighteen hour exposure treatment, regardless of origin, with an average survival of 80%. These results agree with former works that showed high survival of freshwater ostracods under hypoxia (Hagerman 1969; Rossi et al. 2002), although others have stated Ostracoda can be very sensitive to low DO levels (Rosseti et al. 2004; Ruiz et al. 2013). A migratory behavior towards oxygen-rich microhabitats was described by many authors as an adaptation of ostracods to hypoxia (Hagerman 1969; Corbari et al. 2004; Corbari et al. 2005), especially because they seem incapable of regulating their oxygen uptake according to DO availability (Corbari et al. 2004; Corbari et al. 2005). Although no evidence was found in the literature for anaerobic metabolism in ostracods (this study; Rossi et al. 2002), some species contain hemoglobin (Fox 1957), which may assist their survival under hypoxia.
Gastropods did not differ in survival by habitat of origin and had relatively high survival rates under hypoxia. Calow (1975) showed around 60% survival after five days of anoxia for *Ancylus fluviatilis* and up to 80% after weeklong anoxia for *Planorbis contortus* (values estimated from his figure 7). Animals in this group can be air- or water-breathers or both, and although some species might rely on their access to the atmosphere (Penha-Lopes et al. 2010; Seuffert and Martin 2010), some, even pulmonates, do not (this study; Burky and Burky 1977; Hanley and Ultsch 1999). The presence of hemoglobin was considered unimportant for *Planorella duryi* and *Helisoma aniceps*, since they showed similar responses to hypoxia as non-hemoglobin-bearing species (Hanley and Ultsch 1999). Also, pulmonate and prosobranch snails did not differ in their responses to hypoxia (Hanley and Ultsch 1999). No papers were found demonstrating the occurrence of anaerobic metabolism in Gastropoda, so their survival is more likely to be related to their great capacity of regulating their oxygen consumption under varying DO concentrations (Hanley and Ultsch 1999).

Planarians also showed high resistance to hypoxia and no effect of origin in these experiments; however, Rivera and Perich (1994) identified DO as the most critical out of six variables affecting survival and reproduction of four species of planarians (*Dugesia dorotocephala, D. tigrina, Cura foremanni* and *Dendrocelopsis vaginatus*). Their experiments consisted of a two week exposure to different levels of DO, and none of the species survived the 0 and 2 mg.L\(^{-1}\) DO levels. In this shorter-term (18 hours) hypoxia treatment though, planarians were very successful. Some flatworms contain hemoglobin (Crompton and Smith 1963), but no studies were found reporting the occurrence of anaerobic metabolism in these animals.
Macroinvertebrates inhabiting hypoxic macrophyte beds such as TNA beds in the Hudson have two alternatives to cope with the hypoxic habitat within the beds: they can escape to more oxygenated micro-habitats, or possess adaptations to survive through hypoxia. The first alternative was not available for the animals in this experiment, so with the exception of Zygoptera, which must survive hypoxia by escaping to oxygenated zones, all other groups tested must have adaptations to survive hypoxia in place. Some groups in these experiments (Gastropoda, Ostracoda, Planariidae) displayed the same ability to survive hypoxia whether their habitat requires them to do so (TNA beds) or not (SAV). On the other hand, Chironomidae and Amphipoda inhabiting TNA beds seem to have been selected by their better resistance to hypoxia than their relatives in SAV.

Because of their engineering activities on DO, macrophyte beds can impose challenges as well as benefits for the macroinvertebrates that live there. Whether through their regular dark respiration and daylight photosynthesis or growth form-related DO fluctuations, large macrophyte beds represent habitats with abiotic filters that may require specific adaptations of organisms. The results show that these challenges can be met in several different ways by macroinvertebrates: probable movement to nearby oxygenated habitats by zygopterans, short-term (6-18 hour) tolerance of hypoxia by amphipods and chironomids, and long-term (>18 hour) tolerance of hypoxia by gastropods, ostracods and planarians. The fact that different invertebrates meet the challenge of hypoxia in different ways means that different kinds of hypoxic macrophyte beds may support different assemblages of macroinvertebrates. Specifically, the spatial and temporal extent of hypoxia will be critical (whether well-oxygenated refuges are nearby, or whether the hypoxia lasts for longer than the invertebrate can tolerate). Likewise, shifts in
macrophyte species composition caused by species invasions or other reasons may have
differential effects on macroinvertebrates that are caused by different oxygen regimes.
ACKNOWLEDGEMENTS

I would like to acknowledge the Hudson River Foundation and the Tibor T. Polgar Fellowship Program for funding this research and Dr. David L. Strayer for the opportunity to work with him and his valuable advising. I am also deeply grateful to Mary P. Budd for her help in sampling, sorting of organisms and especially for the great time we had while working together. I am also grateful to David T. Fischer, Paul T. Henne and all Cary Institute’s personnel, who were always welcoming and willing to help, and my advisor in Brazil Dr. Sidinei M. Thomaz for always encouraging me to move forward in science.
